Abstract:

Context and purpose of the study - The interest in understanding the water balance of terrestrial plants under drought has led to the creation of the isohydric/anisohydric terminology. The classification was related to an implication-driven framework, where isohydric plants maintain a constant and high leaf water potential through an early and intense closure of their stomata, hence risking carbon starvation. In contrast, anisohydric plants drop their leaf water potential to low values as soil drought is establishing due to insensitive stomata and thus risk mortality through hydraulic failure, albeit maximizing carbon intake. When applied to grapevines, this framework has been elusive, yielding discrepancies in the classification of different wine grape varieties around the world. There is a need to assess different wine grape varieties under the same growing conditions to enable conclusions on the differences in their response to drought and facilitate variety-specific irrigation management.

Material and methods – The vineyard was located in the ROZA irrigation district in the Yakima valley, Washington. Varieties were grown side by side and replicated 8 times. Spacing was 1.8 m x 2.7 m in a North-South orientation. The vines were on their own-roots, double-trunked, trained to a bi-lateral cordon. 12-18 varieties of wine grape grown were studied for this experiment. Access tubes were installed for soil moisture measurements using a neutron probe, and irrigation was independently controlled for each row. Dry-down cycles were applied pre- and post-veraison from 2016 to 2018. On the same day, predawn (Ψ_{pd}) and midday leaf water potential (Ψ_{md}) were measured with a pressure chamber, stomatal conductance (g_s) was measured with a porometer at midday and on the same leaf in 2016 and 2017 and with an infrared gas analyzer in 2018. Soil moisture measurements were taken on the same day for each vine.

Results - The results show that there may be three distinctive major patterns of midday leaf water potential response to soil water availability: Linear drop across the entire soil moisture range such as for Cabernet franc and Semillon, linear drop below a threshold of soil moisture such as for Gewurztraminer and Grenache, and an insensitive to soil moisture such as for Lemberger and Riesling. Meanwhile, the stomatal sensitivity did not always mirror the Ψ_{md} behavior; for example some varieties like Cabernet franc show a linear drop of Ψ_{mid} while having a tight stomatal control during soil drought ($r=0.76$) while other varieties like Riesling have an insensitive response of Ψ_{mid} ($r=0.33$) without necessarily having sensitive stomata ($r=0.56$). Finally, the slope of the linear $\Psi_{md}:\Psi_{pd}$, studied as an the indicator of the internal regulation of water status, varied between 0.4 for Grenache and 1 for Semillon. This shows that for our vineyard, transpiration sensitivity was always higher than hydraulic sensitivity. Since intense yellowing of leaves has been recorded in varieties like Cabernet franc, Muscat blanc and Malbec, these results direct us to inspect if the sensitivity of g_s in those varieties is leading to carbon starvation during drought. These results may eventually be used by growers to devise variety-specific irrigation management strategies.

1. Introduction

ISOHYDRIC AND ANISOHYDRIC BEHAVIOR OF 18 WINE GRAPE VARIETIES GROWN IN AN ARID CLIMATE

Joelle Martinez and Markus Keller

Background
 One of the characteristics of wine grape growing is the ability to work with different varieties leading to the availability of an interesting spectrum of wine flavors and styles. Despite the varetal diversity in Washington, irrigation management strategies have failed to evolve in parallel and the main approach for water application is an FDI program customized to fit either Red or white varieties. Many growers have reported that many varieties show peculiar responses making their irrigation management somewhat ambiguous. Moreover the question of the response of different varieties to vapor pressure deficit (VPD) needs to be investigated to gain knowledge on peculiar behaviors during the frequent summer heat waves.

THE TRADITIONAL CLASSIFICATION

Grenache-like varieties: high stomatal conductance at high VPD, stomata close earlier

Syrah-like varieties: stomata close earlier, stomatal conductance decreases linearly and later, stomata close later

Soil moisture

Typical pattern of varietal behaviors in winegrapes described in the literature (Schultz, 2003)

Does this mean we need to water the anisohydric varieties more?

Do the isohydric varieties have their photosynthesis (sugar production) affected during drought more than the anisohydric varieties?

To what extent do winegrape varieties respond to a VPD increase?

Field Results

LINEAR DROP: Semillon, Cabernet Sauvignon, Grenache, Nebbiolo, Pinot gris, Pinot noir, Sauvignon blanc

CROP AFTER A PLATEAU: Grenache, Cabernet, Pinot, Gewürztraminer, Malbec, Petit Verdot, Merlot

Insensitive: Lemberger, Riesling

Correlation between stomatal conductance and soil moisture at midday. VPD was the most important predictor for stomatal conductance for most of the 18 varieties. Data points are Means \pm SD (n=200).

Pot approach

8 Rootstock/cultivar combinations: Deciduous Syrah on Syrah, Grenache on Grenache, Syrah on Grenache and Grenache on Syrah and Gouais-rooted Syrah and Grenache

2 Growth climates: High VPD environment (GC2) and low VPD environment (GC4), soil moisture kept at field capacity (FC)

Measurements: Ψ_{midday} , $\Psi_{pre-dawn}$, diurnal gs and soil moisture

Pot Results

	p-value Maximal stomatal conductance	p-value Minimal stomatal conductance
VPD	< 0.0001***	< 0.0001***
Rootstock/cultivar combination	0.433	0.227

An increase of VPD from 15 to 28 kPa caused a 3-fold decrease in stomatal conductance while soil moisture was maintained at FC

VPD was found to affect stomatal conductance at any point of the day and independently of the rootstock/cultivar combination

- Take home messages**
- There are 3 patterns of midday Ψ_{midday} evolution with soil moisture that are depicted in Fig 1
 - Varieties that have low midday Ψ_{midday} with a linear drop don't always close their stomata late unless they start with a low gs. However, they always have their stomata tracking midday Ψ_{midday}
 - An increase in VPD causes a decrease in gs independently of the variety and despite the presence of high soil moisture

Field Approach

Field experiment: Dry/down watering cycles applied for 12-16 varieties

Measurements: midday Ψ_{midday} , pre-dawn $\Psi_{pre-dawn}$, stomatal conductance gs and soil moisture

Year: 2015, 2016, 2017 and 2018

The special design of the IAREC vineyard

THE TRADITIONAL UNDERSTANDING

All varieties with LINEAR DROP OF midday Ψ_{midday} will have INSENSITIVE STOMATA TO SOIL DEPLETION

OUR RESULTS CHALLENGE THIS LONG ACCEPTED UNDERSTANDING

- Some varieties with LINEAR DROP OF midday Ψ_{midday} have HIGHLY SENSITIVE STOMATA TO SOIL DEPLETION (SEMILLON)
- Some varieties with NON LINEAR DROP OF midday Ψ_{midday} have INSENSITIVE STOMATA THAT DO NOT CLOSE EARLY (LEMBERGER, MERLOT, GRENACHE)
- The higher the variety starts the more sensitive it will be to soil depletion
- ALL VARIETIES THAT HAVE LOW MINIMAL midday Ψ_{midday} have HIGHLY SENSITIVE STOMATA to midday Ψ_{midday} value (plant water status)
